ABSTRACT

The activation of heteromeric and homomeric nicotinic acetylcholine receptors was studied in Xenopus laevis oocytes to identify key structures of putative agonist molecules associated with the selective activation of homomeric α7 receptors. We observed that selectivity between α7 and α4β2 was more readily obtained than selectivity between α7 and α3β4. Based on structural comparisons of previously characterized selective and nonselective agonists, we hypothesize at least three chemical motifs exist that, when present in molecules containing an appropriate cationic center, could be associated with the selective activation of α7 receptors. We identify the three distinct structural motifs based on prototypical drugs as the choline motif, the tropane motif, and the benzylidene motif. The choline motif involves the location of an oxygen-containing polar group such as a hydroxyl or carbonyl separated by two carbons from the charged nitrogen. The tropane motif provides α7-selectivity based on the addition of multiple small hydrophobic groups positioned away from the cationic center in specific orientations. We show that this motif can convert the nonselective agonists quinuclidine and ethyltrimethyl-ammonium to the α7-selective analogs methyl-quinuclidine and diethylmethyl-ammonium, respectively. We have shown previously that the benzylidene group of 3–2,4, dimethoxy-benzylidene anabaseine (GTS-21) converts anabaseine into an α7-selective agonist. The benzylidene motif was also applied to quinuclidine to generate another distinct family of α7-selective agonists. Our results provide insight for the further development of nicotinic therapeutics and will be useful to direct future experiments with protein structure-based modeling and site-directed mutagenesis.
lacking in the muscle β1 and the neuronal α5 and β3 subunits, so these have been identified as “structural subunits” (Gotti et al., 2006).

At least two emergent properties are likely to have come from the specialization of the non-α subunits in the agonist binding sites. These two properties are the failure of heteromeric receptors to be activated efficiently by the ACh precursor choline (Papke et al., 1996), and the conversion of the

## Structural Diversity of α7-selective agonists

![Diagram showing structural diversity of selective activators of α7 nAChR.](image)

**Fig. 1.** Structural diversity of selective activators of α7 nAChR. Multiple structural classes of nicotinic agonists are represented. Circled compounds are α7-selective. Compounds in filled gray circles had no significant agonist activity when tested at 300 μM on α7, α4β2, or α3β4 receptors (data not shown).

</table>
receptors to desensitized states with high affinity for agonist, in parallel to or after activation (Higgins and Berg, 1988; Buisson and Bertrand, 2001). These features are common to all heteromeric nAChRs, including muscle-type receptors. In contrast to the heteromeric receptors, for the homomeric $\alpha 7$ receptors of the brain, choline is a fully efficacious agonist, and $\alpha 7$ receptors do not convert to high-affinity desensitized states.

The homomer-forming subunit $\alpha 7$ has been identified as phylogenetically ancestral to the more specialized subunits of the heteromeric receptors, and as such it contains subdomains able to contribute to either the primary or complimentary faces of up to five agonist binding sites per receptor (Le Novere et al., 2002a). Although some unique biophysical properties may emerge from the presence of so many potential agonist binding sites (Papke et al., 2000), it is presumably the lack of certain specializations in the binding site that has made it relatively easy to identify agonists that will activate $\alpha 7$ receptors but not heteromeric receptors like those containing $\alpha 4$ and $\beta 2$ or $\alpha 3$ and $\beta 4$.

Our conceptual approach has been to classify “core agonist” structures because they represent different elaborations of the simplest cationic center of tetramethyl-ammonium (TMA). We have arranged into nine structurally related families of agonists, compounds that have been functionally characterized in the published literature by ourselves or others, or in unpublished studies conducted in our laboratory (Fig. 1). Agonists that selectively activate $\alpha 7$ nAChR have been identified in most of the structural classes. Table 1 provides summaries of the function studies that have been conducted on these various compounds.

In addition to choline, a relatively simple structure associated with selective activation of $\alpha 7$ receptors is that of tropane (Papke et al., 2005a). We have published recently that unsubstituted quinuclidine will activate $\alpha 7$ receptors (Papke, 2006), and, as shown in Fig. 1, a quinuclidine provides the core agonist cationic center for many structurally complex $\alpha 7$-selective agonists. In the present study, we evaluate in greater detail the activity of choline and the simple amines TMA and ethyltetramethyl-ammonium (ETMA) and extend a preliminary report (Leonic et al., 2007) on quinuclidine and related compounds. Although quinuclidine itself is not $\alpha 7$-

![Fig. 2.](image)

A, Responses to ACh and choline obtained from single cells expressing either $\alpha 7$, $\alpha 4\beta 2$, or $\alpha 3\beta 4$ nAChR. Note that for $\alpha 7$, the 300 $\mu$M control is a fully efficacious ACh concentration for the net charge response. Choline is approximately 10-fold less potent than ACh, and therefore, 3 mM choline evokes nearly identical responses with 300 $\mu$M ACh. For $\alpha 4\beta 2$, the 30 $\mu$M ACh control is approximately the EC$_{50}$ value for peak current, and 3 mM choline evokes responses that are only 2% of the ACh maximum. For $\alpha 3\beta 4$, the 100 $\mu$M ACh control is approximately the EC$_{50}$ value for peak current, and 3 mM choline evokes peak currents that are approximately 5% of the ACh maximum. B, responses to ACh and QN obtained from single cells expressing either $\alpha 7$, $\alpha 4\beta 2$, or $\alpha 3\beta 4$ nAChR. Note that for $\alpha 7$, the 300 $\mu$M control is a fully efficacious ACh concentration for the net charge response but not for peak current. QN is more potent than ACh and therefore evokes a larger peak current but the same net charge. For $\alpha 4\beta 2$, the 30 $\mu$M ACh control is approximately the EC$_{50}$ value for peak current, and for $\alpha 3\beta 4$, the 100 $\mu$M ACh control is approximately the EC$_{50}$ value for peak current.
selective, we report that hydrophilic side groups, as well as both minimal and large hydrophobic substitutions, affect the activity profile of quinuclidines and can promote selectivity for the activation of $\alpha_7$.

Methods and Materials

Synthetic Chemistry. Solvents and reagents were purchased from Aldrich Chemical (Milwaukee, WI) and Acros Organics (Fairlawn, NJ). All solvents were dried overnight over CaH$_2$ and were freshly distilled before use. $^1$H and $^{13}$C NMR spectra were obtained using VXR 300, Gemini 300 and 500, or Mercury 300 (300 MHz) spectrometers (Varian, Palo Alto, CA) in CDCl$_3$, CD$_3$OD, or D$_2$O solvents. EI Mass spectra were obtained on a Finnigan MAT 95Q spectrometer (Thermo Fisher Scientific, Waltham, MA), or ESI spectra were obtained on a Bruker APEX II FTICR mass spectrometer (Bruker, Newark, DE). NMR spectral data for the new compounds synthesized are included in the supplemental material.

1-Methyl-1-azoniabicyclo[2.2.2]octane Iodide. To prepare 1-methyl-1-azoniabicyclo[2.2.2]octane Iodide (MQN) (Chen and Benoiton, 1976; Kaminski et al., 1978), a mixture of methyl iodide (0.54 ml), KHCO$_3$ (0.34 g), and quinuclidine hydrochloride (50 mg) was stirred in methanol (6.8 ml) at room temperature for 12 h. The solvent was evaporated, and CHCl$_3$ was added to the residue, and the mixture was stirred overnight. The mixture was filtered and the solvent evaporated under vacuum to afford methyl quinuclidine iodide as a white solid (85 mg) in 99% yield (m.p. 230°C, dec). $^1$H NMR (D$_2$O): $\delta$ (in parts per million) 2.01 (m, 6H), 2.20 (m, 1H), 2.93 (s, 3H),

Fig. 3. The effect of ACh, TMA, ETMA, and choline on $\alpha_7$ and $\alpha_{3\beta_4}$ nAChR subtypes. Concentration-response curves for $\alpha_7$-expressing oocytes were calculated based on net charge and those for $\alpha_{3\beta_4}$ responses on peak current amplitudes. Responses were calculated relative to ACh control responses obtained from the same cells (see Materials and Methods) and subsequently normalized to the ACh maximum response determined in separate experiments (data not shown). Values represent the averages (± S.E.M.) of at least four oocytes.

Fig. 4. Structural comparisons of nicotinic agonists. A, we have reported previously that the relatively simple tropane and DMPP molecules shown in the top row are selective activators of a7-receptors, and the overlay of these structures (second row, left) shows a similar disposition of the charge center and hydrophobic substituents. QN, which is not a7-selective, is compared with tropane (second row, right). This comparison suggests the addition of a methyl group to QN to produce MQN (B) would make a better match to the common features of tropane and DMPP. B, structures of EQN, BQN compounds, and other quinuclidines as discussed in the text.

[44x402]the reaction afforded N-ethyl quinuclidine iodide as a white solid (81 mg) in 90% yield (m.p. 210°C, dec). 1H NMR (D2O): δ (parts per million) 1.31 (t, 3H), 2.01 (m, 6H), 2.22 (m, 1H), 3.22 (q, 2H), 3.40 (t, 4H); 13C NMR (D2O): δ (parts per million) 60.0, 54.5, 23.6, 19.5, and 7.6. Modeling. Molecular models of agonists were constructed with the Chem3D Ultra program (Cambridge Scientific, Cambridge, MA). The structures obtained were optimized with the molecular mechanics force field within Chem3D; in some cases, semiempirical calculations with AM1 parameters were used. Conformational searching was used to ensure that high-energy local minima were not used for the overlay calculations. Estimates of common molecular features between groups of agonists were made by using the overlay routine resident within the program suite. The positively charged nitrogen atom found in all agonists was always used as one of the pairs of points used to generate the overlaid structures.

Clustal Analysis. Clustal is an online utility to generate DNA or protein sequence alignments and comparisons. Binding loop protein sequences of α4β2, α3β4, and α7 were submitted to ClustalW2 online at The European Bioinformatics Institute web site (available at http://www.ebi.ac.uk/tools/clustalw2). Specifically, sequence of loops A, B, and C of the α was attached to the sequence of loops D, E, and F of the β or α7. Sequences selected for α4β2 and α3β4 were homologous to the loop sequence indicated for α7 (Stokes et al., 2004) and the acetylcholine binding protein (Brejc et al., 2001).

ACh Receptor Clones. The human nAChR receptor clones were obtained from Dr. Jon Lindstrom (University of Pennsylvania, Philadelphia, PA).

Preparation of RNA. After linearization and purification of cloned cDNAs, RNA transcripts were prepared in vitro using the appropriate mMessage mMachine kit from Ambion Inc. (Austin, TX).

Expression in Xenopus laevis Oocytes. Mature (>9 cm) female X. laevis African frogs (Nasco, Ft. Atkinson, WI) were used as a

![Fig. 5](https://example.com/f5.png)

Fig. 5. The effect of quinuclidine compounds on α7 and α3β4 nAChR subtypes. Concentration-response curves for α7-expressing oocytes were calculated based on net charge and those for α3β4 responses on peak current amplitudes. Responses were calculated relative to ACh control responses obtained from the same cells (see Materials and Methods) and subsequently normalized to the ACh maximum response determined in separate experiments (data not shown). Values represent the averages (± S.E.M.) of at least four oocytes.
source of oocytes. Before surgery, the frogs were anesthetized by placing them in a 1.5 g/l solution of MS222 for 30 min. Oocytes were removed from an incision made in the abdomen. Harvested oocytes were treated with 1.25 mg/ml collagenase (Worthington Biochemical Corporation, Freehold, NJ) for 2 h at room temperature in calcium-free Barth’s solution (88 mM NaCl, 1 mM KCl, 2.38 mM NaHCO3, 0.82 mM MgSO4, 15 mM HEPES, pH 7.6, and 12 mg/l tetracycline) to remove the follicular layer. Stage 5 oocytes were isolated and injected with 50 nl (5–20 ng) of each subunit cRNA. Recordings were normally conducted 2 to 5 days after injection.

Electrophysiology. Experiments were conducted using OpusXpress 6000A (Molecular Devices, Sunnyvale, CA). OpusXpress is an integrated system that provides automated impalement and voltage clamp of up to eight oocytes in parallel. Both the voltage and current electrodes were filled with 3 M KCl. The oocytes were clamped at a holding potential of −60 mV.

Data were collected at 50 Hz and filtered at 20 Hz. The oocytes were bath-perfused with Ringer’s solution. Agonist solutions were delivered from a 96-well plate using disposable tips. Flow rates were set at 2 ml/min for α7 and 4 ml/min for α4β2 and α3β4. Drug applications alternated between ACh controls and test solutions of ACh or other experimental agonists at varying concentrations.

Experimental Protocols and Data Analysis. Responses of α7 receptors are calculated as net charge (Papke and Papke, 2002), and responses of wild-type β subunit-containing receptors are reported as peak currents. Each oocyte received initial control applications of ACh, then experimental drug applications, and follow-up control applications of ACh. For α7 receptors, the control ACh concentration was 300 μM, a concentration sufficient to evoke a maximal net charge response (Papke and Papke, 2002). For α4β2 and α3β4 receptors, the ACh control was 100 μM. Responses to experimental drug applications were calculated relative to the preceding ACh control responses to normalize the data, compensating for the varying levels of channel expression among the oocytes. Mean values and standard errors (S.E.M.) were calculated from the normalized responses of at least four oocytes for each experimental concentration. For concentration-response relations, data were plotted using KaleidaGraph 3.0.2 (Abelbeck Software, Reading, PA), and curves were generated from the Hill equation: response = (I_{max}[agonist]^{nH}) / (I_{max} + [agonist]^{nH}), where I_{max} denotes the maximal response for a particular agonist/subunit combination, and nH represents the Hill coefficient. I_{max}, nH, and the EC_{50} value were all unconstrained for the fitting procedures, except in the case of the ACh response curves. Because ACh is our reference full agonist, for the ACh concentration-response curves, the data were normalized to the observed ACh maximum, and the I_{max} of the curve fits were constrained to equal one.

Results

Choline and Quinuclidine Activation of α7, α4β2, and α3β4 nAChR. The only known α7-selective agonist naturally occurring in the vertebrate nervous system is choline, and, as published previously, choline is a full agonist with potency 10-fold lower than that of ACh. As shown in Fig. 2A, although choline is highly selective for α7, it does produce small but detectable responses from both α4β2 and α3β4 nAChR. When normalized to the maximal ACh-evoked responses in these cell types, the α3β4 were significantly more sensitive to choline than were the α4β2 receptors (p < 0.01), with responses to 3 mM choline equal to 4.5 ± 0.6% (n = 3) and 2.3 ± 0.3% (n = 5) of the ACh maximum for α3β4 and α4β2, respectively.

Quinuclidine (QN) is a fully efficacious agonist of α7 receptors (Papke, 2006) and is a core element of many large α7-selective agonists (Fig. 1). We tested the agonist activity of QN on α3β4 and α4β2 nAChR, and, as shown in Fig. 2B, 300 μM QN was capable of producing maximal activation of α7. At this concentration, QN evoked currents from α4β2 receptors that were only 3.2 ± 0.7% of the ACh maximal responses (n = 5), whereas for α3β4 receptors, the QN-evoked responses were 46 ± 2% of the ACh maximum.

Our observations therefore suggest that to identify the key elements for an α7-selective agonist, comparisons between α7 and α3β4 will be of more use than comparisons between α7 and α4β2. A similar observation has been published pre-

![Fig. 6. Effects of EQN on cells expressing α7 and un.injected cells. Only α7-injected cells showed response to the application of 300 μM ACh. In contrast, inward currents were evoked by 1 mM EQN in both α7-injected and uninject ed cells. However, in α7-injected cells, some portion of the current was mecamylamine-sensitive. The rightmost shows the EQN-evoked currents in the absence and presence of 100 μM mecamylamine.](image-url)
viously (Efange et al., 2001) regarding piperidyl- and pyrroli-
dyl-chromans, which activated α7 and α3-containing nAChR
much more efficaciously than α4-containing receptors. A
Clustal analysis (Higgins, 1994) of α7, α3β4, and α4β2 se-
queneces in the putative ACh binding loops (comparing α7 to
α4 and α3 in loops A, B, and C and to β2 and β4 in loops D,
E, and F; Brejc et al., 2001) indicated slightly greater se-
quence similarity between α7 and α3β4 than between α7 and
α4β2. For these reasons, we focused our studies on α7 and
α3β4 receptors. A good selectivity profile between these two
subtypes will also have the therapeutic value of providing
drugs with few potential side effects caused by the activation
of ganglionic nAChR.

Activity Profiles for TMA, ETMA, Choline, and ACh
on α7 and α3β4. It has been reported previously that TMA
and ETMA activate multiple subtypes of neuronal nAChR
(Papke et al., 1996) when applied at high (1 mM) concen-
trations. Figure 3 shows full concentration-response studies for
these compounds and for ACh and choline on α7 and α3β4
receptors (curve fit values provided in Table 2). All four of
these quaternary amines were full agonists for α7, with only
choline showing a significant decrease in potency compared
with ACh. In contrast, both TMA and ETMA were only par-
tial agonists of α3β4 receptors and also showed reduced po-
tency compared with ACh (Table 2), whereas the activity of
choline for α3β4 was too low to be characterized in regard to
potency.

Activity of Small Quinuclidine-Based Molecules on
α7 and α3β4 nAChR. QN is an effective activator of α7 (Fig.
2B) and a partial agonist of α3β4 (Fig. 5). As shown in Fig.
4A, QN is comparable in size to the α7-selective agonists
tropane and DMP (Papke et al., 2005a). However, although
overlays of DMP and tropane show reasonably good align-
ment of the charged nitrogen and hydrophobic elements, the
overlay of tropane and QN highlights the absence of a small
hydrophobic element common to tropane and DMP, a single
methyl group. We therefore sought to test the hypotheses
that the addition of a methyl group to QN in a similar
position (MQN, Fig. 4B) would produce a loss of α3β4 ac-
tivity. Additional QN-related structures are also included in
Fig. 4B.

As shown in Fig. 5, QN was a potent and fully efficacious
agonist for α7 and a partial agonist for α3β4, with an efficacy
of 64% that of ACh. MQN was also fully effective for activat-
ing α7, although it was less potent than QN. With the addi-
tion of a methyl group to the QN core, essentially all activity
was lost for α3β4 receptors, consistent with the pharmacoph-
ore hypothesis discussed above. It is interesting that the addi-
tional oxygen of quinuclidinone (QN-O) or the hydroxyl
group of quinuclidinol (QN-OH) also caused a loss of α3β4
activation, and the spacing of these polar groups from
the amine center of QN corresponds to the distance of the
hydroxyl from the charged nitrogen in choline. QN-O and
QN-OH were also reduced in efficacy for α7 compared
with QN, and both showed decreases in potency compared
with QN that were equal to (in the case of QN-O) or greater
than (in the case of QN-OH) the potency difference between
ETMA and choline for α7.

Ethyl-quinuclidine (EQN, Fig. 4) was also synthesized and
tested (Fig. 6) to determine whether a somewhat larger hy-
drophobic extension in that domain would improve α7 ago-
nist activity. EQN evoked receptor-specific current in α7-
injected cells. However, it also evoked receptor-independent
currents, which could be recorded in both injected and unin-
jected cells. The nAChR-mediated current could be identified
because it was eliminated by the coapplication of 100 μM
mecamylamine. In α7-injected cells, the mecamylamine-sen-
sitive current was 58 ± 3% of the total current evoked by
the application of 1 mM EQN (n = 4), and the net charge of
the mecamylamine-sensitive current was only 23 ± 2% of that
of the current evoked by the application of 300 μM ACh to
the same cells. EQN also evoked currents in cells injected
with α3β4, but these currents were comparable with the current
evoked in uninjected oocytes and were not blocked by
mecamylamine (data not shown). Therefore, although our
data suggest that EQN is a weak partial agonist for α7
nAChR, the ability of EQN to activate receptor-independent
currents limited our ability to study this agent in detail using
the X. laevis oocyte expression system. Although it is clearly
outside the scope of these experiments to investigate the
nAChR-independent currents evoked by EQN in detail, we
did wish to determine whether mediators of the response

Fig. 7. The effects of dEdMA on cells expressing α7 and α3β4. Representa-
tive traces are shown at the top compared with control ACh responses
obtained from the same cells. For α7, the 300 μM control is a fully
efficacious ACh concentration for the net charge response. For α3β4, the
100 μM ACh control is approximately the EC45 value for peak current.
Concentration-response relationships are shown below. Values represent
the averages (± S.E.M.) of at least four oocytes.
might be muscarinic AChRs, sometimes endogenously expressed by oocytes. Therefore, we compared the responses of uninjected oocytes with 1 mM EQN in Ringer’s solution with or without our normal 1 μM atropine and determined that the responses of uninjected oocytes to EQN were not significantly different in the presence or absence of the mAChR antagonist atropine (data not shown).

Selective Activation of α7 nAChR by Diethyl, Dimethyl Ammonium. Because the addition of a single methyl group was sufficient to convert QN into an α7-selective agonist, we hypothesized that a similar modification to the structure of ETMA would produce decreased activity on α3β4 receptors without a large decrease in α7 activation. As shown in Fig. 7, 300 μM diethyldimethylammonium (dEdMA) produced only approximately 2% activation of α3β4 receptors, and even at a concentration of 3 mM, α3β4 responses were only approximately 6% of the ACh maximum. In contrast to the greater than 10-fold difference in efficacy for α3β4, for α7, dEdMA was 90% as efficacious as ACh and only 2.5-fold less potent compared with ETMA.

Activity of Benzylidene Quinuclidines on α7 and α3β4 nAChR. Although the addition of only a methyl group was sufficient to increase the α7-selectivity for a quinuclidine-based agonist, larger hydrophobic groups are also often tolerated in α7-selective agonists, often improving potency (Papke et al., 2005a), or, depending on additional side groups, affecting both potency and efficacy (Papke et al., 2004a). The conjugation of benzylidene groups to the nonselective agonist anabaseine account for the α7-selectivity of GTS-21 (also known as DMXBA) and related compounds (Papke et al., 2004a). Therefore we

Fig. 8. The effect of benzylidene-quinuclidine compounds on α7 and α3β4 nAChR subtypes. Concentration-response curves for α7-expressing oocytes were calculated based on net charge and those for α3β4 responses on peak current amplitudes. Responses were calculated relative to ACh control responses obtained from the same cells (see Materials and Methods) and subsequently normalized to the ACh maximum response determined in separate experiments (data not shown). Values represent the averages (± S.E.M.) of at least four oocytes.
synthesized a series of benzylidene quinuclidines (Fig. 4B) to determine how effectively benzylidene groups would modulate the activity of quinuclidine-based agonists. Note that the relative orientation of the phenyl and quinuclidine groups around the double bond can lead to alternative E and Z structures (Fig. 4B). Both of these isomers were made with either an unsubstituted benzene group (BQNE and BQNZ) or with a methoxy group at the 4 position (MBQNE and MBQNZ). As shown in Fig. 8, the benzylidene quinuclidines in the E configuration were relatively potent α7 partial agonists, although less efficacious than QN or MQN (Table 1). The efficacy for α7 was further reduced for the benzylidene quinuclidines in the Z configuration. Whereas the activity of BQNE and MBQNE was α7-selective, BQNZ also produced significant activation of α3β4 receptors (Fig. 8) that was comparable with the activation of α7-expressing cells.

**Activation and/or Inhibition of 5HT3 Receptors and Other nAChR.** To more fully characterize the selectivity profile of the compounds used for this study, they were also tested at a concentration of 100 μM for their ability to either activate (when applied alone) or inhibit (when coapplied with agonist) 5HT3 receptors, as well as muscle type (α1β1δε) and α4β2 nAChR expressed in oocytes (Table 3). Although most serotonin receptors are G-protein-coupled, 5HT3 receptors are members of the cysteine-loop superfamily of ligand-gated ion channels, and, like α7 nAChR, 5HT3 receptor subunits form functional homomeric assemblies. Some α7-selective agonists characterized previously, such as tropisetron (Macor et al., 2001; Papke et al., 2005a), have been shown to be antagonists of 5HT3 receptors (Table 1). Likewise, benzylidene anabaseines have been shown to interact at these receptors, as either antagonists or partial agonists (Machu et al., 2001).

None of the quinuclidines or linear amines used for the α7 experiments produced detectable activation of 5HT3 receptors in oocytes. However, the benzylidene quinuclidines, like some benzylidene anabaseines, were effective antagonists, suggesting that the benzylidene group may allow these molecules to bind as competitive antagonists to the serotonin receptors.

The only compounds that produced detectable activation of muscle-type nAChRs were the non-α7-selective compounds, QN, TMA, and Z-forms of the benzylidene quinuclidines. These compounds, and to a lesser degree choline, also produced detectable responses in α4β2-expressing oocytes. These results support the classification of dEdMA, MQN, QN-O, QN-OH, and the E forms of the BQN compounds as α7-selective agonists. Several of the compounds that did not activate the muscle-type or α4β2 nAChR were inhibitory in coapplication experiments, suggesting that they may bind to but fail to activate these receptors or may have channel-blocking properties. Benzylidene anabaseines have been reported to both displace cytosine binding from α4β2-type receptors in brain membranes (Meyer et al., 1997) and produce use-dependent inhibition of α4β2 receptors expressed in *X. laevis* oocytes (Meyer et al., 1998a), so inhibition of these nAChR subtypes by the BQN compounds might be produced by either or both of these mechanisms.

**Modeling of Multiple Pharmacophores for Selective Activation of α7 nAChR.** Figure 9, top, highlights how the nonselective agonist QN can lead to three unique α7-selective agonists. Figure 9, bottom, presents a model for three corresponding structural motifs to achieve selective activation of α7, and a typical (Beers and Reich, 1970) two-point pharmacophore model is represented to illustrate the geometric context of the selectivity model. This model was generated by overlaying a series of α7 agonists and identifying the common disposition of like atom types. Specifically, based on prototypical drugs using these motifs, we can identify them as the choline motif, the tropane motif, and the benzylidene motif. The choline motif involves the location of an oxygen-containing polar group such as a hydroxyl or carbonyl separated by two carbons from the charged nitrogen. Note that the distance between the nitrogen and oxygen is ~3.4 Å, which, for example, in the case of 3-quinuclidinol, is probably too

N, application of the drug at a concentration of 100 μM did not produce responses greater than our level of detection (i.e., distinct from application artifacts of 3-5 nA); N.S., there was no significant inhibition of the coapplication responses compared with control applications of agonist alone.
short to correspond to the hydrogen bond acceptor group described in existing nAChR pharmacophore models (Beers and Reich, 1970; Sheridan et al., 1986; Tonder et al., 2001). We therefore consider this selectivity motif to be distinct from the aforementioned pharmacophoric element.

The tropane motif relies on the recognition of small hydrophobic groups in a geometric relationship quite distinct from the benzylidine motif (discussed below). This motif is centered around the ammonium pharmacophore as illustrated in Fig. 9, bottom. The improvement in \( \alpha 7 \)-selectivity obtained with the addition of a methyl group to quinuclidine and ethyltrimethyl-ammonium supports the hypothesis that tropane and other small selective agonists such as 1,1-dimethylpiperididine use a common (tropane) motif. This point is supported by the molecular overlay of QN and tropane shown in Fig. 4.

Like the tropane motif, the benzylidine motif is based on recognition of a hydrophobic group. However, it is spatially distinct from the tropane site. We consider that the \( \alpha 7 \) recognition site for this motif is extended in length, on the order of 7 to 10 Å from the charged nitrogen common to all agonists. This estimate is based on the inspection of models of benzylidene anabaseine, cinnamylidene anabaseine, and BQNE, in which the distance from the charged nitrogen to the end of the aromatic ring was measured. Furthermore, because substituents on this aromatic ring can modulate the activity of the agonist, the receptor pocket recognizing the benzylidene motif is likely to include residues that provide discrimination in addition to simple recognition of the aromatic ring system. It is interesting that the bridged nicotine analog ACME (Fig. 1) may provide an indication that the benzylidene selectivity filter could “start” as close as 3.7 Å from the charged nitrogen. In ACME, which is \( \alpha 7 \)-selective, the ethyl chain, which constrains the pyridine ring from free rotation, is approximately in the same location as the benzylic carbon in compounds like benzylidene anabaseine and BQNE (Papke et al., 2005b).

![Figure 9](image)

**Fig. 9.** A. Three unique modifications of a nonselective agonist lead to selectivity. Quinuclidine is a nonselective \( \alpha 7 \) agonist, but its 3-hydroxy, 3-benzylidene, and \( N \)-methyl analogs are \( \alpha 7 \)-selective. B, spatial model for \( \alpha 7 \)-selectivity filters. Three key recognition motifs are superimposed on an arbitrary Cartesian frame of reference to illustrate the spatial relationships between the motifs. Red signifies the universal ammonium (cationic) recognition motif for all nAChRs and the H bond acceptor of the classic nAChR pharmacophore. The dark blue region represents the small tropane motif, which recognizes small aliphatic groups. The small light blue region represents the choline motif, a putative hydrogen bond acceptor. Green represents the benzylidene motif, an extended region that accommodates planar aromatic moieties. C, \( \alpha 7 \)-selective agonists superimposed on the spatial model. The top row (tropane motif) compares MQN, DMP, and tropane, illustrating that a common element is a small hydrophobic group resting above the x-y plane. The \( N \)-methyl group may serve to position the agonist to take advantage of this binding pocket. The bottom row (benzylidene motif) compares EBQN with BA. The common element for these two \( \alpha 7 \)-selective agonists is an aromatic group in the third quadrant of the x-y plane.
**Discussion**

Although certain features have been proposed to be common to most \( \alpha 7 \)-selective agonists, the diversity of ligands identified to be \( \alpha 7 \)-selective is impressive (Mazurov et al., 2006). In general, drugs in commercial development have a cationic center, a hydrogen bond acceptor group, and one or more hydrophobic elements. The first two of these features were postulated in the earliest models for the pharmacophore for the muscle-type nAChR (Beers and Reich, 1970) and hence are not associated with \( \alpha 7 \)-selectivity. However, the effective activation of both heteromeric and homomeric neuronal nAChRs by the simple quaternary amine TMA means that, although a hydrogen bond acceptor group may improve the activity for a specific type of ligand, it is not part of the minimal pharmacophore of a nonselective \( \alpha 7 \) agonist. The key element for \( \alpha 7 \) selectivity would then seem to be, in most cases, specific hydrophobic element(s). Most of the \( \alpha 7 \)-selective agonists shown in Fig. 1 have very large hydrophobic groups, and many may be grouped into common classes based on the size and position of the groups. However, we have reported previously that the size of the hydrophobic element(s) need not be large (Papke et al., 2004b, 2005a,b). The data of the present study support the hypothesis that a hydrophobic element as small as a single methyl group can provide selective activation of \( \alpha 7 \) nAChR. Furthermore, this small hydrophobic recognition element is distinct from the one recognizing large hydrophobic residues. Our results therefore suggest that there are at least three independent and distinct structural motifs that can be associated with \( \alpha 7 \)-selective agonists, which we have identified as the choline motif, the tropine motif, and the benzylidene motif.

Although agonists with the choline motif such as choline, QN-O, and QN-OH can selectively activate \( \alpha 7 \) receptors, the potency of these drugs is typically at least 10-fold lower than related agonists that lack the oxygen group (e.g., ETMA and QN). In the case of the QN compounds, there was also decreased efficacy in the \( \alpha 7 \)-selective compounds using the choline motif. The choline motif is also present in four other inactive compounds closely related to \( \alpha 7 \) agonists (gray in Fig. 1), N-methyl-3-piperidinol, N,N-dimethyl-3-piperidinol, 1-(2-hydroxyethyl)piperidine, and 1-(2-hydroxyethyl)pyrrolidine (data not shown). In the case of N-methyl-3-piperidinol and N,N-dimethyl-3-piperidinol, the hydroxyl group resides in a piperidine ring with a chair-like conformation. Though structurally similar to QN-OH, this latter compound places the six-membered piperidine ring in a boat-like conformation because of the bridgehead. This alters and locks the orientation of the hydroxyl group, which could reasonably be critical for activity. In the case of the hydroxyethyl compounds, the choline motif is entirely exocyclic, and thus the attached five-

![Fig. 10. Comparison of synthesized compounds with known \( \alpha 7 \)-selective and nonselective agonists. The comparison illustrates how known quinuclidine-selective agonists can be classified in terms of whether they use a selectivity pharmacophore. The relative orientation of molecules coincides with the framework shown in Fig. 9. A, a comparison of AR-R17779 (blue) with QNOH (red), which share the choline motif. C, the Z-isomer of BQN places the phenyl ring close to the region occupied by the pyridine ring of nonselective anabaseine. D, overlay of BQNE and anabaseine. There was failure to match the benzylidene motif with the pyridine ring of anabaseine with any reasonable overlay scheme. In C and D, the red molecules are the BQN isomers, the blue molecule is anabaseine (AB).](molpharm.aspetjournals.org)
or six-membered ring structure may clash with the receptor in seeking to bind favorably.

Because, the α7-selective compounds using the choline motif all seem to be less potent and/or efficacious for α7 than their most closely related nonselective analogs, the choline motif for α7-selectivity seems to apply some cost to functionality. One hypothesis is that perhaps the polar groups of choline and of more complex nonfunctional choline analogs such as tropine make a spurious hydrogen bond with the receptor that impedes the proper orientation of the ammonium analog in the binding site, reducing binding affinity and/or potency for activation. Comparison of AR-R17779 and 3-hydroxy quinuclidine by overlay shows nearly identical overlap (Fig. 10A). Because AR-R17779 cannot function as a hydrogen bond donor, it would avoid the spurious H-bond problem, and it is noteworthy that if AR-R17779 is modified so its oxygen atom becomes an H-bond donor (NH group) or a CH₂ group, α7 binding affinity is abolished (Mullen et al., 2000). On the other hand, functional groups of the receptor-bound drugs may interfere with the conformational changes required for channel gating, and although this would not necessarily affect binding affinity for the resting state of the receptor, it might affect potency for activation. In summary, features of the choline motif that may strongly disfavor binding and/or activation of heteromeric receptors, may only do so mildly for α7.

The tropane motif provides α7-selectivity via recognition of small hydrophobic groups clustered about the ammonium nitrogen. Given that methylpiperidine is not α7-selective, but the addition of the second N-methyl group in the axial position above the piperidine ring plane renders it α7-selective, we suggest that the selectivity of MQN may not arise from the methyl group directly, but rather the methyl group may position the agonist so that the bridgehead CH₂CH₂CH₂ unit fits into the tropane motif of the receptor. In tropane itself, a similar effect may be operative. Furthermore, this tropane motif might be hypothesized to be the basis for other α7-selective agonists such as 3-acetoxy-1,1-dimethyl-piperidine. However, it is also present in DMPP, which is not α7-selective. Although DMPP has two nitrogens, the phenyl-substituted one is not basic, so an alternate binding mode with this position bearing the positive charge seems unlikely. It is possible that in binding to a non-α7 receptor, the phenyl group of DMPP provides a pathway for receptor activation that is unavailable to a simple piperidine. Whether or not this is the case for DMPP, it is quite clear that the position of the phenyl group with respect to the ammonium pharmacophore is quite critical because, as we discuss below, α7 selectivity can be conferred to a member of the quinuclidine family by the addition of a benzylidene group.

The third selectivity motif we identify is the benzylidene motif, in part because we have directly shown that the addition of a benzylidene group to quinuclidine in the BQN series can confer selectivity. Just as significant is the historic precedent of the first large family of synthetic α7-selective agonists, the benzylidene anabaseine such as GTS-21 (Papke et al., 2004a). In all probability, homologs of this motif account for the α7-selectivity of agonists such as PNU-282987, SSR180711, and others in Fig. 1 that have correspondingly large hydrophobic elements. Indeed, the molecular overlay of BQNE and SSR180711 shows an excellent coincidence of the aromatic moieties, using the charged nitrogen as an anchor point. (Fig. 10B).

The configuration of the double bond in the benzylidene motif is important for selective activation of α7 and significantly affects both the potency and efficacy of BQNs, because the E-isomers seem to be not only more selective but also more potent and efficacious (Table 1). However, this is only a modest difference, leading to the possibility that the recognition site in α7 for the benzylidene motif may be able to accommodate either geometric isomer. Another possibility is that the benzylidene motif does not apply to the Z-isomers. Instead, in the QNZ compounds, the phenyl ring may locate in the same region of the receptor occupied when agonists like nicotine or anabaseine are bound, using the “aryl-centroid” pharmacophoric site (Sheridan et al., 1986). BQNZ and the nonselective agonist AB were compared by overlaying the two structures, and we found that the aryl ring of BQNZ but not the aryl ring of BQNE, resided close to the pyridine ring of anabaseine. (Fig. 10, C and D). This and all of the preceding comparative analyses are predicated on the simplifying idea that a common single productive binding mode leading to activation exists. If this is not the case, comparative analysis would become exceptionally complex. The latter possibility is supported by mutational studies of the conserved Tyr188 residue in α7 and α4β2 (Horenstein et al., 2007). This residue has been hypothesized to play a key role in the sequence of intramolecular events coupling agonist binding to channel gating (Mukhtasimova et al., 2005). However, although the mutation of tyrosine 188 to phenylalanine had a large effect on ACh potency in α7, it had no effect on the potency of the benzylidene anabaseine 4OH-GTS-21 efficacy or potency in α7 (Horenstein et al., 2007). Further support for the hypothesis that gating can be initiated through multiple mechanisms came from the observation that the corresponding tyrosine to phenylalanine mutation in α4β2 had little apparent effect on activation by ACh but produced a 200-fold increase in the efficacy of 4OH-GTS-21.

The model presented in Fig. 9 incorporates the disposition of selectivity motifs in a relative sense, but ultimately, we seek to map this model into the receptor via mutagenesis studies, scanning cysteine accessibility mutagenesis analyses, homology modeling, and docking studies, in lieu of direct crystallographic data for α7 and α3β4 receptors. Preliminary inspection of homology models for α7 based on the crystal structure of snail ACh binding protein suggest that the large benzylidene motif will require extended interactions at the subunit interface. Ongoing work will address why heteromeric receptors cannot accommodate the aforementioned selectivity motifs in the activated state of the receptor and what the specific interactions are with α7. The results reported in this study demonstrate that α7-selective agonists may be obtained by swapping a subset of molecular features of one agonist class with another, for example, conferring selectivity to a quinuclidine by addition of a benzylidene group. This portability can be exploited for the design and synthesis of new α7 agonists.
